VQE Potential Energy Surface & 3D Molecular Orbital Renderer: Full Research & Implementation Report

---

Part 1 — Theoretical Foundations

1. Quantum Chemistry from First Principles

1.1 The Molecular Hamiltonian Under the Born-Oppenheimer Approximation

The full non-relativistic Hamiltonian for a molecule with N_e electrons and N_n nuclei is (in atomic units, $\hbar = m_e = e = 4\pi\epsilon_0 = 1$):

$$\hat{H}_{\text{mol}} = \hat{T}_n + \hat{T}_e + \hat{V}_{nn} + \hat{V}_{en} + \hat{V}_{ee}$$

where:

$$\hat{T}_n = -\sum_{A=1}^{N_n} \frac{1}{2M_A} \nabla_A^2 \qquad \text{(nuclear kinetic energy)}$$

$$\hat{T}_e = -\sum_{i=1}^{N_e} \frac{1}{2} \nabla_i^2 \qquad \text{(electronic kinetic energy)}$$

$$\hat{V}_{nn} = \sum_{A<B} \frac{Z_A Z_B}{|\mathbf{R}_A - \mathbf{R}_B|} \qquad \text{(nuclear-nuclear repulsion)}$$

$$\hat{V}_{en} = -\sum_{i=1}^{N_e} \sum_{A=1}^{N_n} \frac{Z_A}{|\mathbf{r}_i - \mathbf{R}_A|} \qquad \text{(electron-nuclear attraction)}$$

$$\hat{V}_{ee} = \sum_{i<j} \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|} \qquad \text{(electron-electron repulsion)}$$

Here M_A and Z_A are the mass and atomic number of nucleus A, $\mathbf{R}_A$ are nuclear coordinates, and $\mathbf{r}_i$ are electron coordinates.

The **Born-Oppenheimer (BO) approximation** exploits the mass ratio $m_e/M_A \sim 10^{-3}$–10^{-5}: nuclei are vastly heavier than electrons, so electrons respond instantaneously to nuclear motion. Under this separation, the total wavefunction factorises:

$$\Psi(\mathbf{r}, \mathbf{R}) \approx \psi_{\text{el}}(\mathbf{r}; \mathbf{R}) \cdot \chi_{\text{nuc}}(\mathbf{R})$$

where ψ_{el} depends parametrically on nuclear positions $\mathbf{R}$. The **electronic Hamiltonian** at fixed nuclear geometry is:

$$\hat{H}_{\text{el}}(\mathbf{R}) = \hat{T}_e + \hat{V}_{en} + \hat{V}_{ee} + \hat{V}_{nn}$$

(the nuclear repulsion $\hat{V}_{nn}$ is a constant at fixed $\mathbf{R}$). Solving the electronic Schrödinger equation:

$$\hat{H}_{\text{el}}|\psi_k(\mathbf{R})\rangle = E_k(\mathbf{R})|\psi_k(\mathbf{R})\rangle$$

yields the electronic energy $E_k(\mathbf{R})$ as a function of nuclear coordinates — this is the **potential energy surface (PES)**.

1.2 The Electronic Structure Problem: Exponential Complexity

The electronic wavefunction $\psi_{\text{el}}(\mathbf{r}_1, \sigma_1, \dots, \mathbf{r}_{N_e}, \sigma_{N_e})$ is a function of $3N_e$ spatial coordinates and N_e spin variables. For fermions, it must be antisymmetric under particle exchange.

Given a basis of M spin-orbitals $\{\phi_p\}$, the Hilbert space of N_e electrons occupying M orbitals has dimension $\binom{M}{N_e}$. For $M = 100$ orbitals and $N_e = 20$ electrons, $\binom{100}{20} \approx 5.4 \times 10^{20}$ — this is the Full Configuration Interaction (FCI) dimension. Storing a single FCI vector at double precision would require $\sim 4 \times 10^9$ TB. This exponential scaling is why classical exact diagonalisation is intractable beyond ~ 20 orbitals and is the fundamental motivation for quantum computing approaches.

1.3 Second-Quantized Hamiltonian

In second quantisation, we introduce creation $\hat{a}_p^\dagger$ and annihilation $\hat{a}_p$ operators for each spin-orbital ϕ_p, satisfying the fermionic anti-commutation relations:

$$\{\hat{a}_p, \hat{a}_q^\dagger\} = \delta_{pq}, \qquad \{\hat{a}_p, \hat{a}_q\} = 0, \qquad \{\hat{a}_p^\dagger, \hat{a}_q^\dagger\} = 0$$

The electronic Hamiltonian becomes:

$$\hat{H}_{\text{el}} = \sum_{p,q} h_{pq}\, \hat{a}_p^\dagger \hat{a}_q + \frac{1}{2} \sum_{p,q,r,s} h_{pqrs}\, \hat{a}_p^\dagger \hat{a}_q^\dagger \hat{a}_s \hat{a}_r + E_{\text{nuc}}$$

where:

- **One-electron integrals** (kinetic energy + electron-nuclear attraction):

$$h_{pq} = \int \phi_p^*(\mathbf{x}) \left(-\frac{1}{2}\nabla^2 - \sum_A \frac{Z_A}{|\mathbf{r} - \mathbf{R}_A|} \right) \phi_q(\mathbf{x})\, d\mathbf{x}$$

- **Two-electron integrals** (electron-electron repulsion, in chemists' notation):

$$h_{pqrs} = \iint \frac{\phi_p^*(\mathbf{x}_1)\phi_r(\mathbf{x}_1)\phi_q^*(\mathbf{x}_2)\phi_s(\mathbf{x}_2)}{|\mathbf{r}_1 - \mathbf{r}_2|}\, d\mathbf{x}_1\, d\mathbf{x}_2$$

Here $\mathbf{x} = (\mathbf{r}, \sigma)$ denotes combined spatial and spin coordinates. The two-electron integrals in **physicists' notation** (antisymmetrised) are:

$$\langle pq||rs\rangle = h_{pqrs} - h_{pqsr}$$

$E_{\text{nuc}} = \hat{V}_{nn}$ is the constant nuclear repulsion energy at the given geometry.

The number of one-electron integrals scales as $O(M^2)$ and two-electron integrals as $O(M^4)$. These integrals are computed classically by quantum chemistry packages (PySCF, Psi4, etc.) and serve as input to the quantum algorithm.

1.4 Molecular Orbitals, Basis Sets, and the Fock Matrix

Molecular orbitals (MOs) are expressed as linear combinations of atomic orbitals (LCAO):

$$\phi_p(\mathbf{r}) = \sum_{\mu=1}^{K} C_{\mu p}\, \chi_\mu(\mathbf{r})$$

where $\{\chi_\mu\}$ is the **atomic orbital (AO) basis set** and $C_{\mu p}$ are the MO coefficients obtained by solving the Hartree-Fock equations.

Basis sets approximate the true atomic orbitals with Gaussian-type orbitals (GTOs):

- **STO-3G (Minimal basis):** Each Slater-type orbital (STO) is approximated by 3 Gaussian primitives. For H : 2 basis functions (one per atom). For H O: 7 basis functions (1s, 2s, 2p×3 on O; 1s on each H). This is the smallest possible basis — qualitatively correct but quantitatively poor.
- **6-31G* (Split-valence + polarisation):** Valence orbitals are split into two functions (3+1 Gaussians), core orbitals use 6 Gaussians, and polarisation d-functions are added on heavy atoms. For H O: 19 basis functions. Significantly more accurate, especially for geometries and relative energies.

The **Fock matrix F** in the AO basis is:

$$F_{\mu\nu} = h_{\mu\nu}^{\text{core}} + \sum_{\lambda\sigma} P_{\lambda\sigma} \left[(\mu\nu|\lambda\sigma) - \frac{1}{2}(\mu\lambda|\nu\sigma) \right]$$

where h^{core} is the one-electron (core) Hamiltonian matrix, $P_{\lambda\sigma}$ is the density matrix, and $(\mu\nu|\lambda\sigma)$ are two-electron integrals in the AO basis. The Hartree-Fock equations (Roothaan-Hall equations) are the generalised eigenvalue problem:

$$\mathbf{FC} = \mathbf{SC}\epsilon$$

where $\mathbf{S}$ is the overlap matrix $S_{\mu\nu} = \langle\chi_\mu|\chi_\nu\rangle$ and ϵ contains the orbital energies. This is solved self-consistently (SCF): the Fock matrix depends on the density matrix $\mathbf{P} = \mathbf{C}_{\text{occ}}\mathbf{C}_{\text{occ}}^T$, which depends on $\mathbf{C}$, which comes from diagonalising $\mathbf{F}$.

1.5 Hartree-Fock Theory and Its Failure at Bond Dissociation

Restricted Hartree-Fock (RHF) constrains the wavefunction to be a single Slater determinant:

$$|\Phi_{\text{HF}}\rangle = \hat{a}_1^\dagger \hat{a}_2^\dagger \cdots \hat{a}_{N_e}^\dagger |0\rangle$$

This captures the mean-field electron-electron interaction (each electron moves in the average potential of all others) but misses **correlation energy** — the energy difference between the exact solution and the HF solution:

$$E_{\text{corr}} = E_{\text{exact}} - E_{\text{HF}} < 0$$

HF works well near equilibrium geometries where the single-determinant picture is qualitatively correct. However, it fails catastrophically at bond dissociation because:

1. **Static (strong) correlation:** At large internuclear separation, the correct wavefunction becomes a superposition of multiple determinants. For H dissociation, the exact wavefunction at $R \to \infty$ is:

$$|\Psi\rangle \to \frac{1}{\sqrt{2}}(|\sigma_g\bar{\sigma}_g\rangle - |\sigma_u\bar{\sigma}_u\rangle)$$

(a superposition of doubly-occupied bonding and anti-bonding configurations). RHF forces a single determinant $|\sigma_g\bar{\sigma}_g\rangle$, which incorrectly mixes in ionic terms (H^+H^-) at dissociation, predicting an energy ~ 0.25 Hartree too high.

2. **Dynamic correlation:** Short-range electron-electron cusp conditions are never captured by a single determinant. This contributes a correlation energy typically $\sim 1\%$ of total energy but $\sim 100\%$ of chemical bond energies.

Post-HF methods (MP2, CISD, CCSD(T), FCI) recover correlation energy at increasing computational cost. VQE on a quantum computer can in principle reach FCI accuracy with polynomial quantum resources.

---

2. Fermion-to-Qubit Mappings

2.1 Jordan-Wigner Transformation

The Jordan-Wigner (JW) transformation maps fermionic operators to qubit (Pauli) operators by encoding the occupation of each spin-orbital in a qubit and using Z-strings to enforce anti-commutation:

$$\hat{a}_p^\dagger \mapsto \frac{1}{2}(\hat{X}_p - i\hat{Y}_p) \otimes \prod_{q=0}^{p-1} \hat{Z}_q = \frac{1}{2}\hat{\sigma}_p^- \bigotimes_{q<p} \hat{Z}_q$$

$$\hat{a}_p \mapsto \frac{1}{2}(\hat{X}_p + i\hat{Y}_p) \otimes \prod_{q=0}^{p-1} \hat{Z}_q = \frac{1}{2}\hat{\sigma}_p^+ \bigotimes_{q<p} \hat{Z}_q$$

where $\hat{\sigma}_p^\pm = (\hat{X}_p \mp i\hat{Y}_p)/2$ are the qubit raising/lowering operators and the Z-string $\prod_{q<p} \hat{Z}_q$ provides the fermionic sign (parity of all lower-indexed orbitals).

Verification of anti-commutation: Consider $\hat{a}_p^\dagger \hat{a}_q + \hat{a}_q \hat{a}_p^\dagger$ for $p \neq q$. The Z-strings on the overlapping qubits between p and q introduce a sign flip, yielding:

$$\{\hat{a}_p, \hat{a}_q^\dagger\}_{\text{JW}} = \delta_{pq}\hat{I}$$

as required.

Number operator: $\hat{n}_p = \hat{a}_p^\dagger \hat{a}_p \mapsto \frac{1}{2}(\hat{I} - \hat{Z}_p)$, which has eigenvalue 0 on $|0\rangle$ (unoccupied) and 1 on $|1\rangle$ (occupied).

One-body terms under JW:

$$\hat{a}_p^\dagger \hat{a}_q \mapsto \frac{1}{4}[(\hat{X}_p\hat{X}_q + \hat{Y}_p\hat{Y}_q) + i(\hat{X}_p\hat{Y}_q - \hat{Y}_p\hat{X}_q)] \prod_{k=\min(p,q)+1}^{\max(p,q)-1} \hat{Z}_k$$

For $p = q$: $\hat{a}_p^\dagger \hat{a}_p = \frac{1}{2}(\hat{I} - \hat{Z}_p)$.

The Z-string between indices p and q makes the operator weight (number of Pauli terms) scale as $O(N)$ for distant orbitals. This is the principal cost of JW: non-local operators.

Two-body terms under JW: Each $\hat{a}_p^\dagger \hat{a}_q^\dagger \hat{a}_s \hat{a}_r$ term generates a sum of Pauli strings of weight up to $O(N)$. The total number of Pauli terms in the qubit Hamiltonian scales as $O(M^4)$.

2.2 Parity Mapping

The **parity mapping** (Bravyi-Kitaev parity basis) encodes the parity of the occupation number rather than the occupation itself. Qubit p stores the parity $\bigoplus_{q\leq p} n_q$ (sum modulo 2 of occupations up to orbital p).

The creation operator becomes:

$$\hat{a}_p^\dagger \mapsto \frac{1}{2}\hat{X}_p \bigotimes_{q\in U(p)} \hat{X}_q \cdot \bigotimes_{k\in P(p)} \hat{Z}_k - \frac{i}{2}\hat{Y}_p \bigotimes_{q\in U(p)} \hat{X}_q$$

where $U(p)$ and $P(p)$ are the "update" and "parity" sets determined by the binary tree structure.

Qubit reduction advantage: In the parity basis, the last qubit stores the total parity of the electron number, and the second-to-last stores the total spin parity. For systems with fixed electron number and fixed spin (which is always the case in chemistry), these two qubits are redundant and can be removed, reducing the qubit count by 2:

$$M \text{ spin-orbitals} \to M-2 \text{ qubits (parity mapping with tapering)}$$

This is significant for small molecules: H (STO-3G) goes from 4 qubits (JW) to 2 qubits (parity + tapering).

2.3 Worked Example: H in STO-3G

Setup: H has 2 electrons in a minimal basis of 2 spatial orbitals (σ_g, σ_u) giving 4 spin-orbitals: $\sigma_{g\alpha}$, $\sigma_{g\beta}$, $\sigma_{u\alpha}$, $\sigma_{u\beta}$. This maps to 4 qubits under JW.

Electronic integrals (at equilibrium $R = 0.735$ Å):

Using PySCF to compute the integrals and PennyLane's `qml.qchem` to perform the JW mapping, the qubit Hamiltonian for H (STO-3G) is:

$$\hat{H} = g_0\hat{I}+g_1\hat{Z}_0+g_2\hat{Z}_1+g_3\hat{Z}_2+g_4\hat{Z}_3+g_5\hat{Z}_0\hat{Z}_1+g_6\hat{Z}_0\hat{Z}_2+g_7\hat{Z}_0\hat{Z}_3+g_8\hat{Z}_1\hat{Z}_2+g_9\hat{Z}_1\hat{Z}_3+g_{10}\hat{Z}_2\hat{Z}_3+g_{11}\hat{X}_0\hat{X}_1\hat{Y}_2\hat{Y}_3+g_{12}\hat{X}_0\hat{Y}$$

with numerical coefficients (at $R = 0.735$ Å):

Term	Coefficient (Hartree)
$\hat{I}$	-0.0988
$\hat{Z}_0$	$+0.1711$
$\hat{Z}_1$	$+0.1711$
$\hat{Z}_2$	-0.2232
$\hat{Z}_3$	-0.2232
$\hat{Z}_0\hat{Z}_1$	$+0.1686$
$\hat{Z}_0\hat{Z}_2$	$+0.1205$
$\hat{Z}_0\hat{Z}_3$	$+0.1659$
$\hat{Z}_1\hat{Z}_2$	$+0.1659$
$\hat{Z}_1\hat{Z}_3$	$+0.1205$
$\hat{Z}_2\hat{Z}_3$	$+0.1743$
$\hat{X}_0\hat{X}_1\hat{Y}_2\hat{Y}_3$	-0.0454
$\hat{X}_0\hat{Y}_1\hat{Y}_2\hat{X}_3$	$+0.0454$
$\hat{Y}_0\hat{X}_1\hat{X}_2\hat{Y}_3$	$+0.0454$
$\hat{Y}_0\hat{Y}_1\hat{X}_2\hat{X}_3$	-0.0454

Term	Coefficient (Hartree)

The 15-term qubit Hamiltonian acts on $2^4 = 16$-dimensional Hilbert space. The HF reference state is $|1100\rangle$ (first two spin-orbitals occupied). The FCI ground-state energy at equilibrium is $E_{\text{FCI}} = -1.1373$ Hartree.

With **parity mapping + 2-qubit tapering**, this reduces to a 2-qubit Hamiltonian:

$$\hat{H}_{\text{tapered}} = a_0\hat{I} + a_1\hat{Z}_0 + a_2\hat{Z}_1 + a_3\hat{Z}_0\hat{Z}_1 + a_4\hat{X}_0\hat{X}_1$$

with only 5 terms on 2 qubits — dramatically simpler to simulate.

2.4 Qubit Count and Circuit Depth Comparison

Molecule	Basis	Spatial Orbs	Spin-Orbs (M)	JW Qubits	Parity (tapered)	UCCSD Params	CNOT Depth (UCCSD)
H	STO-3G	2	4	4	2	3	~16
LiH	STO-3G	6	12	12	10	~52	~1200
H O	STO-3G	7	14	14	12	~80	~3000
H O	6-31G*	19	38	38	36	~2000	~80000

The CNOT depth scales roughly as $O(M^3 N_e)$ for UCCSD, making large molecules intractable on NISQ hardware without active space reduction.

---

3. Variational Quantum Eigensolver (VQE)

3.1 The Variational Principle

The variational principle states that for any normalised trial state $|\psi(\theta)\rangle$:

$$E(\theta) = \langle\psi(\theta)|\hat{H}|\psi(\theta)\rangle \geq E_0$$

where E_0 is the exact ground-state energy. This follows directly from expanding $|\psi(\theta)\rangle$ in the eigenbasis $\{|E_k\rangle\}$ of $\hat{H}$:

$$E(\theta) = \sum_k |c_k|^2 E_k \geq E_0 \sum_k |c_k|^2 = E_0$$

since $E_k \geq E_0$ for all k and $\sum_k |c_k|^2 = 1$.

This means any parameterised quantum circuit that prepares $|\psi(\theta)\rangle$ gives an **upper bound** on the ground-state energy. By minimising $E(\theta)$ over θ, we approach E_0 from above. The tightness of the bound depends on the expressibility of the ansatz — whether the parameterised family can represent (or closely approximate) the true ground state.

3.2 The UCCSD Ansatz

Classical Coupled Cluster (CC): The coupled-cluster wavefunction is:

$$|\Psi_{\mathrm{CC}}\rangle = e^{\hat{T}}|\Phi_{\mathrm{HF}}\rangle$$

where $\hat{T} = \hat{T}_1 + \hat{T}_2 + \cdots$ is the cluster operator. For CCSD (Singles and Doubles):

$$\hat{T}_1 = \sum_{i\in\mathrm{occ}} \sum_{a\in\mathrm{virt}} t_i^a \, \hat{a}_a^\dagger \hat{a}_i$$

$$\hat{T}_2 = \sum_{i<j\in\mathrm{occ}} \sum_{a<b\in\mathrm{virt}} t_{ij}^{ab} \, \hat{a}_a^\dagger \hat{a}_b^\dagger \hat{a}_j \hat{a}_i$$

where i, j label occupied orbitals, a, b label virtual (unoccupied) orbitals, and t_i^a, t_{ij}^{ab} are the cluster amplitudes (variational parameters).

Problem for quantum computing: The classical CC operator $e^{\hat{T}}$ is not unitary ($\hat{T}$ is not anti-Hermitian), so it cannot be directly implemented as a quantum circuit.

Unitary Coupled Cluster (UCC): Replace $\hat{T}$ with the anti-Hermitian operator $\hat{T} - \hat{T}^\dagger$:

$$|\Psi_{\mathrm{UCC}}\rangle = e^{\hat{T}-\hat{T}^\dagger}|\Phi_{\mathrm{HF}}\rangle$$

This is manifestly unitary: $\hat{U} = e^{\hat{T}-\hat{T}^\dagger}$ satisfies $\hat{U}^\dagger\hat{U} = \hat{I}$ since $(\hat{T} - \hat{T}^\dagger)^\dagger = -(\hat{T} - \hat{T}^\dagger)$.

For UCCSD:

$$\hat{T} - \hat{T}^\dagger = \sum_{i,a} t_i^a (\hat{a}_a^\dagger \hat{a}_i - \hat{a}_i^\dagger \hat{a}_a) + \sum_{i<j,a<b} t_{ij}^{ab} (\hat{a}_a^\dagger \hat{a}_b^\dagger \hat{a}_j \hat{a}_i - \hat{a}_i^\dagger \hat{a}_j^\dagger \hat{a}_b \hat{a}_a)$$

The number of parameters is $n_{\mathrm{singles}} = N_{\mathrm{occ}} \times N_{\mathrm{virt}}$ plus $n_{\mathrm{doubles}} = \binom{N_{\mathrm{occ}}}{2}\binom{N_{\mathrm{virt}}}{2}$.

3.3 Trotterisation of UCCSD into Gates

The UCC unitary $e^{\hat{T}-\hat{T}^\dagger}$ cannot be decomposed exactly into single/two-qubit gates because the individual excitation operators do not commute. We use the first-order Suzuki-Trotter decomposition:

$$e^{\hat{T}-\hat{T}^\dagger} \approx \prod_\mu e^{\theta_\mu \hat{\tau}_\mu}$$

where $\hat{\tau}_\mu$ are individual excitation generators (single or double), θ_μ are the corresponding amplitudes, and the product is over all excitations.

Single excitation gate: For the excitation $i \to a$:

$$e^{\theta(a_a^\dagger a_i - a_i^\dagger a_a)}$$

Under JW, this maps to a rotation involving X, Y Pauli strings with Z-strings between orbital indices i and a. PennyLane provides `qml.SingleExcitation(theta, wires=[i, a])` which implements this as a Givens rotation:

$$\text{SingleExcitation}(\theta) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos(\theta/2) & -\sin(\theta/2) & 0 \\ 0 & \sin(\theta/2) & \cos(\theta/2) & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

acting on the $\{|01\rangle, |10\rangle\}$ subspace of wires $[i, a]$.

Double excitation gate: For $i, j \to a, b$:

$$e^{\theta(a_a^\dagger a_b^\dagger a_j a_i - a_i^\dagger a_j^\dagger a_b a_a)}$$

PennyLane provides `qml.DoubleExcitation(theta, wires=[i, j, a, b])` which implements a 4-qubit rotation in the $\{|1100\rangle, |0011\rangle\}$ subspace. This gate decomposes into ~ 16 CNOT gates.

Trotterisation error: The first-order Trotter formula has error $O(\sum_{\mu<\nu} \|[\hat{\tau}_\mu, \hat{\tau}_\nu]\| \cdot |\theta_\mu||\theta_\nu|)$. In practice, for VQE, the Trotter error is absorbed into the variational parameters — the optimizer compensates for the discretisation, so the ground-state energy can still be reached if the Trotterised ansatz is expressive enough.

3.4 Hardware-Efficient Ansatz

An alternative to UCCSD is the **hardware-efficient ansatz (HEA)**, which consists of layers of native single-qubit rotations and entangling gates that are directly executable on a given hardware topology:

$$|\psi(\theta)\rangle = \prod_{l=1}^{L} \left[\hat{U}_{\text{ent}} \cdot \prod_{i=1}^{N_q} R_Y(\theta_i^{(l)}) R_Z(\phi_i^{(l)}) \right] |\Phi_{\text{HF}}\rangle$$

where $\hat{U}_{\text{ent}}$ is a layer of CNOT (or CZ) gates following the hardware connectivity.

Advantages over UCCSD: - Much shallower circuits (fewer CNOTs per layer). - No chemistry-specific structure needed — can be used for any Hamiltonian. - Circuit depth is a tunable hyperparameter (number of layers L).

Disadvantages: - No physical motivation: the circuit does not encode any knowledge of the electronic structure problem. - Suffers from barren plateaus more readily as N_q and L increase. -

Does not preserve electron number or spin symmetry unless explicitly constrained. - Convergence to the ground state is not guaranteed (the landscape may have many local minima).

For small molecules (H , LiH), HEA with 1–3 layers can reach chemical accuracy. For larger molecules, UCCSD (or adaptive variants like ADAPT-VQE) is generally superior.

3.5 The Full VQE Loop

1. **State preparation:** Prepare $|\psi(\theta)\rangle = \hat{U}(\theta)|\Phi_{\text{HF}}\rangle$ on the quantum computer.
2. **Measurement:** Measure $\langle\psi(\theta)|\hat{H}|\psi(\theta)\rangle$ by decomposing $\hat{H}$ into Pauli terms:

$$\hat{H} = \sum_k c_k \hat{P}_k$$

   Measure each $\langle\hat{P}_k\rangle$ from repeated preparations + measurements. Group commuting Pauli terms to reduce the number of distinct measurement circuits.
3. **Classical optimization:** Update θ using a classical optimizer (gradient-based or gradient-free) to minimise $E(\theta)$.
4. **Convergence:** Repeat until $|E(\theta^{(k)}) - E(\theta^{(k-1)})| < \varepsilon$ or maximum iterations reached.

The hybrid quantum-classical nature of VQE keeps quantum circuit depth shallow (only state preparation + measurement) while offloading the optimisation to classical hardware. The bottleneck is the number of circuit evaluations needed for sufficient shot statistics and optimiser convergence.

---

4. Potential Energy Surface (PES)

4.1 Definition

The **potential energy surface** (PES) is the electronic energy $E_0(\mathbf{R})$ as a function of nuclear coordinates $\mathbf{R}$:

$$\text{PES} : \mathbb{R}^{3N_n-6} \to \mathbb{R}$$

(subtracting 3 translational and 3 rotational degrees of freedom, or $3N_n - 5$ for linear molecules).

For a diatomic molecule like H , the PES is a one-dimensional curve $E(R)$ where R is the internuclear distance. For polyatomics, the PES is a high-dimensional hypersurface.

4.2 What the PES Reveals

- **Equilibrium geometry R_e:** The minimum of $E(R)$, where $dE/dR = 0$ and $d^2E/dR^2 > 0$. For H , $R_e \approx 0.74$ Å.
- **Dissociation energy D_e:** The energy difference between the minimum and the asymptotic separated-atom limit: $D_e = E(R \to \infty) - E(R_e)$. For H , $D_e \approx 4.75$ eV (exact: 4.7467 eV).
- **Bond stretching frequency ω_e:** Related to the curvature at the minimum: $\omega_e = \sqrt{k/\mu}$ where $k = d^2E/dR^2|_{R_e}$ and μ is the reduced mass.

- **Transition states:** Saddle points on the PES (for polyatomics) correspond to transition states connecting reactants and products.

4.3 Accuracy Hierarchy

The hierarchy of computational chemistry methods, in increasing accuracy and cost:

Method	Scaling	Correlation	PES Quality
HF	$O(M^4)$	None	Fails at dissociation
MP2	$O(M^5)$	Perturbative	Fair near equilibrium, fails at dissociation
CISD	$O(M^6)$	Variational, not size-consistent	Good near equilibrium
CCSD(T)	$O(M^7)$	"Gold standard" of single-ref methods	Excellent near equilibrium
FCI	Exponential	Exact (within basis)	Exact reference
VQE (UCCSD)	Quantum poly	Variational, size-consistent	Approaches FCI

Chemical accuracy is defined as $\Delta E \leq 1.6$ mHartree ≈ 1 kcal/mol ≈ 43 meV. Achieving chemical accuracy across the entire PES (including dissociation) requires a method that correctly handles strong correlation — this is where VQE with a multi-reference-capable ansatz can outperform CCSD(T).

4.4 H Dissociation Curve: The Benchmark

The H molecule is the standard test case for VQE. The exact (FCI/STO-3G) dissociation curve has:

- $R_e = 0.735$ Å, $E(R_e) = -1.1373$ Hartree
- $E(R \to \infty) = -0.9997$ Hartree (two separated hydrogen atoms)
- $D_e = 0.1376$ Hartree $= 3.745$ eV (in STO-3G; the basis set limit value is higher)

RHF failure: At $R = 3.0$ Å, the RHF energy is ~ -0.90 Hartree while the exact energy is ~ -1.00 Hartree — an error of ~ 0.1 Hartree (~ 63 kcal/mol), completely unacceptable.

VQE target: Reproduce the FCI/STO-3G curve to within **chemical accuracy** (1.6 mHartree) at all bond lengths $R \in [0.3, 3.0]$ Å. With the UCCSD ansatz on 4 qubits (or 2 qubits with parity + tapering), this is achievable in noiseless simulation and is the primary validation target.

---

5. Molecular Orbitals and Wavefunction Visualization

5.1 LCAO Expansion

Each molecular orbital is expanded in the AO basis:

$$\phi_p(\mathbf{r}) = \sum_{\mu=1}^{K} C_{\mu p}\, \chi_\mu(\mathbf{r})$$

where χ_μ are Gaussian-type basis functions centred on nuclei:

$$\chi_\mu(\mathbf{r}) = N_\mu\,(x - A_x)^{l_x}(y - A_y)^{l_y}(z - A_z)^{l_z}\,e^{-\alpha_\mu|\mathbf{r}-\mathbf{A}|^2}$$

with angular momentum quantum numbers (l_x, l_y, l_z), exponent α_μ, centre $\mathbf{A}$, and normalisation N_μ. The MO coefficients $C_{\mu p}$ come from the converged HF calculation.

5.2 Evaluating $\psi(\mathbf{r})$ on a 3D Grid

To visualise an MO, evaluate $\phi_p(\mathbf{r})$ on a uniform 3D Cartesian grid:

1. Define the grid: $\mathbf{r}_{ijk} = (x_{\min} + i\Delta x,\ y_{\min} + j\Delta y,\ z_{\min} + k\Delta z)$ for $i = 0, \dots, N_x - 1$, etc. Typical grid: $\Delta x = \Delta y = \Delta z = 0.1$ Bohr, extent ± 5 Bohr from molecular centre, giving $\sim 100^3 = 10^6$ grid points.
2. For each grid point, compute each AO value:
$$\chi_\mu(\mathbf{r}_{ijk}) = N_\mu \prod_d (r_d - A_d)^{l_d} \exp(-\alpha_\mu|\mathbf{r}_{ijk} - \mathbf{A}|^2)$$
3. Contract with MO coefficients:
$$\phi_p(\mathbf{r}_{ijk}) = \sum_\mu C_{\mu p}\,\chi_\mu(\mathbf{r}_{ijk})$$

This produces a **volumetric scalar field** $V_p[i,j,k] = \phi_p(\mathbf{r}_{ijk})$ of shape (N_x, N_y, N_z).

Optimisation: For GTOs, the exponential decay makes most basis functions negligible beyond a few Bohr from their centre. Use a cutoff radius per AO (e.g., where $\chi_\mu < 10^{-8}$) and only evaluate within that radius. The evaluation is vectorised by forming a displacement tensor $\Delta_{g\mu d} = r_{gd} - A_{\mu d}$ of shape $(N_{\text{grid}}, K, 3)$, computing squared distances $|\Delta_{g\mu}|^2 = \sum_d \Delta^2_{g\mu d}$, and evaluating all Gaussians in a single broadcasted exponential $G_{g\mu} = \exp(-\alpha_\mu|\Delta_{g\mu}|^2)$. The angular polynomial prefactors are applied element-wise, and the final MO values are obtained by contracting with MO coefficients: $\phi_p(\mathbf{r}_g) = \sum_\mu C_{\mu p}\,[\text{angular}]_{g\mu}\,G_{g\mu}$.

(Full implementation: `report2_scripts/orbital_grid.py`)

5.3 Electron Density and the One-Particle Reduced Density Matrix

The **electron density** is the sum over occupied MOs:

$$\rho(\mathbf{r}) = \sum_{i\in\text{occ}} n_i\,|\phi_i(\mathbf{r})|^2$$

where n_i is the occupation number (2 for RHF doubly-occupied orbitals). More generally, for a correlated wavefunction with one-particle reduced density matrix (1-RDM) γ_{pq}:

$$\rho(\mathbf{r}) = \sum_{p,q} \gamma_{pq}\,\phi^*_p(\mathbf{r})\phi_q(\mathbf{r})$$

where $\gamma_{pq} = \langle\Psi|\hat{a}^\dagger_p\hat{a}_q|\Psi\rangle$. For VQE, the 1-RDM can be measured on the quantum computer by measuring $\langle\hat{a}^\dagger_p\hat{a}_q\rangle$ in the Pauli basis (each $\hat{a}^\dagger_p\hat{a}_q$ maps to a sum of Pauli strings under JW).

5.4 Isosurface Extraction

An **isosurface** is the set of points where a scalar field equals a constant value:

$$S_c = \{\mathbf{r} : \phi_p(\mathbf{r}) = c\}$$

For MO visualisation, the conventional isovalues are $c = \pm 0.05$ a.u. (atomic units). The positive lobe ($c = +0.05$) shows where the wavefunction is positive; the negative lobe ($c = -0.05$) shows where it's negative. These lobes are typically coloured blue/red respectively.

Why ± 0.05 a.u.? This isovalue encloses approximately 90% of the electron density associated with the orbital, providing a visually useful representation of the orbital shape without being too diffuse (smaller $|c|$) or too compact (larger $|c|$).

The **marching cubes algorithm** (Lorensen & Cline, 1987) extracts a triangle mesh approximating the isosurface from the volumetric data. For each voxel (cube formed by 8 neighbouring grid points):

1. Classify each corner as inside ($\phi > c$) or outside ($\phi < c$) the isosurface.
2. The 8 binary corner classifications give $2^8 = 256$ possible configurations, reduced to 15 unique topological cases by symmetry.
3. Look up the corresponding triangle configuration in a precomputed table (the **marching cubes lookup table**).
4. Interpolate vertex positions along cube edges where the isosurface crosses (linear interpolation between corner values).
5. Compute face normals from the gradient of the scalar field at each vertex (or from the triangle vertices directly).

Module Specifications

1. `molecule.py`

Purpose: Define molecular systems with geometry, basis set, and charge/multiplicity.

This module provides two core data classes and a set of factory/utility functions:

- **`Atom`** — Holds an element symbol (e.g., `'H'`, `'O'`) and a Cartesian position vector (x, y, z) in Ångströms.
- **`MoleculeSpec`** — Aggregates a list of `Atom` objects together with basis set name (default `sto-3g`), net charge (default 0), spin multiplicity $2S + 1$ (default 1 = singlet), and a human-readable name for logging.

Function	Description	Key Parameters	Returns
`create_h2(bond_length)`	Places two H atoms symmetrically along the z-axis at $\pm R/2$.	R in Å (default 0.735)	`MoleculeSpec` for H
`create_lih(bond_length)`	Places Li at the origin and H at distance R along z.	R in Å (default 1.595)	`MoleculeSpec` for LiH
`create_h2o(oh_length, angle_deg)`	Constructs a bent H O geometry with O at the origin and two H atoms placed at bond length R_{OH} and opening angle α.	R_{OH} in Å (default 0.957), α in degrees (default 104.5)	`MoleculeSpec` for H O
`set_bond_length(mol, a, b, new_length)`	Returns a deep copy of `mol` with the distance between atoms `a` and `b` set to `new_length`, keeping the bond midpoint fixed. The direction vector $\hat{\mathbf{d}} = (\mathbf{r}_b - \mathbf{r}_a)/\lVert\mathbf{r}_b - \mathbf{r}_a\rVert$ is preserved while both atoms are displaced symmetrically.	Atom indices, new R in Å	New `MoleculeSpec`

```python
from __future__ import annotations

import copy
from dataclasses import dataclass

import numpy as np

@dataclass
class Atom:
    """A single atom with element symbol and Cartesian position (Å)."""
    symbol: str
    position: np.ndarray  # shape: (3,)

@dataclass
class MoleculeSpec:
    """Full specification of a molecular system."""
    atoms: list[Atom]
    basis: str = "sto-3g"
    charge: int = 0
    multiplicity: int = 1
    name: str = ""

def create_h2(bond_length: float = 0.735) -> MoleculeSpec:
    """Place two H atoms symmetrically along z at ±R/2."""
    ...

def create_lih(bond_length: float = 1.595) -> MoleculeSpec:
    """Place Li at origin and H at distance R along z."""
    ...

def create_h2o(
    oh_length: float = 0.957,
    angle_deg: float = 104.5,
) -> MoleculeSpec:
    """Construct bent HO: O at origin, two H at R_OH and angle  ."""
    ...

def set_bond_length(
    mol: MoleculeSpec,
    atom_idx_a: int,
    atom_idx_b: int,
    new_length: float,
```

```
) -> MoleculeSpec:
    """Return a deep copy with bond a-b set to new_length (Å).

    Preserves bond midpoint and direction unit vector.
    """
    ...
```

(Full implementation: `report2_scripts/molecule.py`)

2. `classical_hf.py`

Purpose: Interface to PySCF for Hartree-Fock calculations, integral extraction, and MO coefficients.

This module wraps PySCF to provide all the classical quantum-chemistry quantities needed downstream. It exposes a result container and four functions:

- **`HFResult`** — Data class bundling everything produced by a converged RHF calculation:
  - Total HF energy E_{HF} and nuclear repulsion energy E_{nuc} (both in Hartree).
  - MO coefficient matrix $\mathbf{C}$ of shape (K, M) where K = number of AO basis functions and M = number of MOs.
  - Orbital energies $\{\epsilon_p\}$ of shape $(M,)$.
  - One-electron integrals h_{pq} in the MO basis, shape (M, M).
  - Two-electron integrals h_{pqrs} in the MO basis, shape (M, M, M, M).
  - AO overlap matrix $\mathbf{S}$ of shape (K, K), electron count N_e, orbital count M, and AO labels.

Function	What it computes	Returns
`run_hartree_fock(mol_spec)`	Builds a PySCF `Mole` object from the `MoleculeSpec`, runs RHF SCF, then extracts the converged Fock matrix $\mathbf{F}$, MO coefficients $\mathbf{C}$, orbital energies $\{\epsilon_p\}$, and transforms the one- and two-electron integrals to the MO basis via $h_{pq} = \mathbf{C}^T \mathbf{h}^{\text{core}} \mathbf{C}$ and the four-index AO-to-MO transformation for h_{pqrs}.	`HFResult`
`get_fci_energy(mol_spec)`	Runs RHF followed by PySCF's Full CI solver to obtain the exact ground-state energy within the given basis.	E_{FCI} (float, Hartree)
`get_cisd_energy(mol_spec)`	Runs RHF + Configuration Interaction Singles and Doubles.	E_{CISD} (float, Hartree)
`get_ccsd_t_energy(mol_spec)`	Runs RHF + CCSD, then adds the perturbative triples correction (T).	$E_{\text{CCSD(T)}}$ (float, Hartree)

```python
from __future__ import annotations

from dataclasses import dataclass

import numpy as np
```

```python
from pyscf import ao2mo, gto, scf, fci, ci, cc

@dataclass
class HFResult:

    ...

def get_ccsd_t_energy(mol_spec: MoleculeSpec) -> float:
    """Run RHF + CCSD(T); return E_CCSD(T) (Hartree)."""
    ...
```

(Full implementation: `report2_scripts/classical_hf.py`)

3. `hamiltonian_builder.py`

Purpose: Build the qubit Hamiltonian from molecular integrals using Jordan-Wigner or Parity mapping. Cross-validate with QuTiP exact diagonalisation.

This module converts classical molecular integrals into a qubit-operator representation suitable for

VQE, and provides an independent validation path.

- **`QubitHamiltonian`** — Data class holding the PennyLane Hamiltonian object, qubit count N_q, number of Pauli terms, the mapping name (`'jordan_wigner'` or `'parity'`), and an optional exact ground-state energy for validation.

Function	Description
`build_hamiltonian(h_pq, h_pqrs, n_electrons, E_nuc, mapping, ...)`	Assembles the second-quantised fermionic Hamiltonian $\hat{H} = \sum_{pq} h_{pq} \hat{a}_p^\dagger \hat{a}_q + \frac{1}{2} \sum_{pqrs} h_{pqrs} \hat{a}_p^\dagger \hat{a}_q^\dagger \hat{a}_s \hat{a}_r + E_{\text{nuc}}$ from the supplied MO-basis integrals, then applies the chosen fermion-to-qubit mapping (Jordan-Wigner or parity) via PennyLane. Optionally restricts to an active space of the specified number of active electrons and orbitals. Returns a `QubitHamiltonian`.
`validate_with_qutip(qubit_hamiltonian)`	Converts the PennyLane Hamiltonian to a QuTiP `Qobj`, performs exact diagonalisation, and returns the ground-state energy E_0. This provides an independent check that the fermion-to-qubit mapping is correct.
`pennylane_to_qutip(hamiltonian, n_qubits)`	Maps each Pauli string $c_k \hat{P}_k$ in the PennyLane Hamiltonian to a tensor product of QuTiP Pauli matrices ($\hat{\sigma}_x$, $\hat{\sigma}_y$, $\hat{\sigma}_z$, $\hat{I}$), accumulating into a single QuTiP `Qobj` of dimension $(2^{N_q}, 2^{N_q})$.

```python
from __future__ import annotations

from dataclasses import dataclass

import numpy as np
import pennylane as qml
import qutip

@dataclass
class QubitHamiltonian:
    """Container for a qubit Hamiltonian and metadata."""
    hamiltonian: qml.Hamiltonian
    n_qubits: int
    n_paulis: int
    mapping: str
    fci_energy: float | None = None

def build_hamiltonian(
    one_electron_integrals: np.ndarray,
    two_electron_integrals: np.ndarray,
```

```
    n_electrons: int,
    nuclear_repulsion: float,
    mapping: str = "jordan_wigner",
    active_electrons: int | None = None,
    active_orbitals: int | None = None,
) -> QubitHamiltonian:
    """Assemble fermionic Hamiltonian from MO integrals and map to qubits.

    Supports Jordan-Wigner and parity mappings via PennyLane.
    Optionally restricts to an active space.
    """
    ...

def validate_with_qutip(qubit_hamiltonian: QubitHamiltonian) -> float:
    """Convert to QuTiP Qobj, diagonalise, return ground-state energy E ."""
    ...

def pennylane_to_qutip(
    hamiltonian: qml.Hamiltonian,
    n_qubits: int,
) -> qutip.Qobj:
    """Map PennyLane Pauli Hamiltonian to a QuTiP Qobj of dim (2^N, 2^N)."""
    ...
```

(Full implementation: `report2_scripts/hamiltonian_builder.py`)

4. `ansatz.py`

Purpose: Construct UCCSD and hardware-efficient ansätze using PennyLane.

This module provides two ansatz constructors, each returning a callable circuit function and a parameter count.

> **`build_uccsd_ansatz(n_qubits, n_electrons, hf_state=None)`** constructs the Unitary Coupled Cluster Singles and Doubles ansatz. It first enumerates all spin-allowed single excitations $\{(i \to a)\}$ and double excitations $\{(i, j \to a, b)\}$ using PennyLane's `qchem.excitations`. The UCCSD unitary is:
>
> $$|\Psi(\theta)\rangle = e^{\hat{T}(\theta) - \hat{T}^\dagger(\theta)} |\Phi_{\text{HF}}\rangle$$
>
> where $\hat{T} = \hat{T}_1 + \hat{T}_2$ with $\hat{T}_1 = \sum_{i,a} \theta_i^a \hat{a}_a^\dagger \hat{a}_i$ and $\hat{T}_2 = \sum_{i<j,a<b} \theta_{ij}^{ab} \hat{a}_a^\dagger \hat{a}_b^\dagger \hat{a}_j \hat{a}_i$. PennyLane's `qml.UCCSD` (or individual `SingleExcitation` / `DoubleExcitation` gates) compiles this into a gate sequence via first-order Trotterisation. The HF reference state fills the first N_e spin-orbitals (or uses a user-supplied binary vector). Returns `(ansatz_fn, n_params, excitation_list)`.
>
> **`build_hardware_efficient_ansatz(n_qubits, n_layers=2, entangler='CNOT')`** builds a hardware-efficient ansatz consisting of L layers, each comprising $R_Y(\theta)$ and

$R_Z(\phi)$ rotations on every qubit followed by a ladder of CNOT (or CZ) entangling gates on nearest-neighbour pairs. The total parameter count is $2N_qL$. Returns `(ansatz_fn, n_params)`.

```python
from __future__ import annotations

from typing import Callable

import numpy as np
import pennylane as qml

def build_uccsd_ansatz(
    n_qubits: int,
    n_electrons: int,
    hf_state: np.ndarray | None = None,
) -> tuple[Callable, int, list]:
    """Construct UCCSD ansatz from PennyLane qchem excitations.

    Returns (ansatz_fn, n_params, excitation_list).
    ansatz_fn accepts a parameter array of shape (n_params,).
    """
    ...

def build_hardware_efficient_ansatz(
    n_qubits: int,
    n_layers: int = 2,
    entangler: str = "CNOT",
) -> tuple[Callable, int]:
    """Build L-layer hardware-efficient ansatz (RY, RZ + entangler).

    Total parameters: 2 * n_qubits * n_layers.
    Returns (ansatz_fn, n_params).
    """
    ...
```

(Full implementation: `report2_scripts/ansatz.py`)

5. `vqe_solver.py`

Purpose: VQE optimisation loop with multiple optimiser backends.

- **`VQEResult`** — Data class storing the best energy E^* (Hartree), optimal parameters θ^*, full trajectory $(\theta^{(k)}, E^{(k)})$ at each iteration, total iteration count, convergence flag, and gradient norms.

  `run_vqe(hamiltonian, ansatz_fn, n_params, n_qubits, ...)` executes the VQE optimisation loop. A PennyLane QNode wraps the ansatz and evaluates $E(\theta) = \langle\psi(\theta)|\hat{H}|\psi(\theta)\rangle$. The solver supports four optimiser backends:

- **Adam / GradientDescent**: PennyLane built-in optimisers using automatic differentiation (backprop or parameter-shift).
- **COBYLA**: SciPy's derivative-free constrained optimiser.
- **SPSA** (Simultaneous Perturbation Stochastic Approximation): estimates the gradient from two function evaluations per step via random perturbation $\hat{g}_k = \frac{f(\theta+c_k\Delta)-f(\theta-c_k\Delta)}{2c_k\Delta}$ with decaying step sizes $a_k = a_0/(k+A)^\alpha$ and $c_k = c_0/k^\gamma$.

Convergence is declared when $|E^{(k)} - E^{(k-1)}| < \varepsilon$. Initial parameters default to zero with a small random perturbation to break symmetry. An optional callback is invoked each iteration with `(iteration, params, energy)`.

```python
from __future__ import annotations

from dataclasses import dataclass
from typing import Callable

import numpy as np
import pennylane as qml

@dataclass
class VQEResult:
    """Container for VQE optimisation results."""
    optimal_energy: float
    optimal_params: np.ndarray
    trajectory: list[tuple[np.ndarray, float]]
    n_iterations: int
    converged: bool
    gradient_norms: list[float]

def run_vqe(
    hamiltonian: qml.Hamiltonian,
    ansatz_fn: Callable,
    n_params: int,
    n_qubits: int,
    init_params: np.ndarray | None = None,
    optimizer: str = "Adam",
    learning_rate: float = 0.05,
    maxiter: int = 200,
    tol: float = 1e-6,
    device_name: str = "default.qubit",
    diff_method: str = "backprop",
    callback: Callable | None = None,
) -> VQEResult:
    """Run the VQE optimisation loop.

    Supports Adam, GradientDescent, COBYLA, and SPSA backends.
```

```
    Convergence declared when |ΔE| < tol.
    """
    ...
```

(Full implementation: `report2_scripts/vqe_solver.py`)

6. `pes_scanner.py`

Purpose: Sweep over bond lengths, run VQE at each geometry, collect PES data.

- **`PESData`** — Data class holding arrays of bond lengths (Å), VQE energies, HF energies, FCI energies, and optionally CISD and CCSD(T) energies, plus the list of optimal VQE parameter vectors at each geometry.

  `scan_pes(molecule_factory, bond_lengths, ...)` iterates over an array of bond lengths $\{R_1, \dots, R_N\}$. At each R_k it:

  1. Calls `molecule_factory(R_k)` to build the geometry.
  2. Runs Hartree-Fock via `run_hartree_fock` to extract integrals.
  3. Builds the qubit Hamiltonian via `build_hamiltonian`.
  4. Constructs the chosen ansatz (UCCSD or hardware-efficient).
  5. Runs VQE, optionally **warm-starting** from the previous geometry's optimal parameters θ^*_{k-1} to accelerate convergence along the scan.
  6. Optionally computes HF, CISD, CCSD(T), and FCI energies via `classical_hf` for comparison.

  The warm-start strategy exploits the fact that molecular orbitals change smoothly with geometry, so θ^*_{k-1} is a good initial guess for θ^*_k.

```python
from __future__ import annotations

from dataclasses import dataclass
from typing import Callable

import numpy as np

@dataclass
class PESData:
    """Container for PES scan results."""
    bond_lengths: np.ndarray
    energies_vqe: np.ndarray
    energies_hf: np.ndarray
    energies_fci: np.ndarray
    energies_cisd: np.ndarray | None = None
    energies_ccsd_t: np.ndarray | None = None
    vqe_params: list[np.ndarray] | None = None

def scan_pes(
    molecule_factory: Callable[[float], MoleculeSpec],
```

```
    bond_lengths: np.ndarray,
    basis: str = "sto-3g",
    mapping: str = "jordan_wigner",
    ansatz_type: str = "uccsd",
    optimizer: str = "Adam",
    maxiter: int = 200,
    use_prev_params: bool = True,
    compute_classical: bool = True,
    callback: Callable | None = None,
) -> PESData:
    """Sweep bond lengths, run VQE at each geometry, collect PES data.

    Warm-starts from previous geometry's optimal parameters when
    use_prev_params is True and parameter count is unchanged.
    """
    ...
```

(Full implementation: `report2_scripts/pes_scanner.py`)

7. `orbital_grid.py`

Purpose: Evaluate molecular orbital wavefunctions on a 3D Cartesian grid.

- **`OrbitalVolumeData`** — Data class holding the 3D scalar field array of shape (N_x, N_y, N_z), grid origin, grid spacing (all in Bohr), grid shape, and the MO index.

  `evaluate_orbital_on_grid(mo_coefficients, orbital_index, atom_coords, atom_symbols, basis_name, grid_extent=5.0, grid_spacing=0.1)` computes the MO wavefunction $\phi_p(\mathbf{r})$ on a uniform Cartesian grid. The grid extends $\pm$`grid_extent` Bohr from the molecular centre in each direction with spacing `grid_spacing`. At each grid point $\mathbf{r}_g$, PySCF's `eval_gto` evaluates all AO basis functions $\{\chi_\mu(\mathbf{r}_g)\}$ efficiently (exploiting Gaussian sparsity), then contracts with the p-th column of the MO coefficient matrix:

  $$\phi_p(\mathbf{r}_g) = \sum_\mu C_{\mu p}\, \chi_\mu(\mathbf{r}_g)$$

  The result is reshaped into a 3D volume of shape (N_x, N_y, N_z).

  `evaluate_electron_density(mo_coefficients, n_occupied, ...)` computes the total RHF electron density on the same grid type by summing over occupied spatial orbitals:

  $$\rho(\mathbf{r}) = \sum_{i=0}^{N_{\text{occ}}-1} 2\,|\phi_i(\mathbf{r})|^2$$

  The factor of 2 accounts for double occupation in RHF. Returns an `OrbitalVolumeData` with `orbital_index = -1` to indicate a density rather than a single orbital.

```
from __future__ import annotations

from dataclasses import dataclass

import numpy as np
```

```python
from pyscf import gto

@dataclass
class OrbitalVolumeData:
    """Volumetric data for a molecular orbital on a 3D grid."""
    values: np.ndarray           # shape: (N_x, N_y, N_z)
    grid_origin: tuple[float, float, float]    # in Bohr
    grid_spacing: tuple[float, float, float]   # in Bohr
    grid_shape: tuple[int, int, int]
    orbital_index: int

def evaluate_orbital_on_grid(

    Returns OrbitalVolumeData with orbital_index = -1.
    """
    ...
```

(Full implementation: `report2_scripts/orbital_grid.py`)

8. `isosurface.py`

Purpose: Marching cubes isosurface extraction from volumetric data.

- **`IsosurfaceMesh`** — Data class holding a triangle mesh: vertex positions $(N_v, 3)$, vertex normals $(N_v, 3)$, face index triples $(N_f, 3)$, and a per-vertex sign array ($+1$ for positive lobe, -1 for negative lobe) used for colouring.

  `marching_cubes(volume, isovalue, grid_origin, grid_spacing)` extracts the isosurface $S_c = \{\mathbf{r} : \phi(\mathbf{r}) = c\}$ from a 3D scalar field using scikit-image's implementation of the Lorensen & Cline (1987) algorithm. Each voxel's 8 corners are classified as inside/outside the isosurface, yielding an 8-bit index into a lookup table of 256 triangulation cases (15 unique topologies). Edge-crossing positions are linearly interpolated, and vertex normals are computed from the scalar field gradient. Vertices are translated to world coordinates by adding the grid origin.

  `extract_dual_isosurface(volume, isovalue, grid_origin, grid_spacing)` calls `marching_cubes` twice — once at $+c$ and once at $-c$ — then concatenates the two meshes. Vertices from the positive isosurface are tagged with sign $= +1$; negative with sign $= -1$. Face indices of the negative mesh are offset by the vertex count of the positive mesh before concatenation.

```python
from __future__ import annotations

from dataclasses import dataclass

import numpy as np
from skimage.measure import marching_cubes as sk_marching_cubes

@dataclass
class IsosurfaceMesh:
    """Triangle mesh from isosurface extraction."""
    vertices: np.ndarray    # shape: (N_v, 3)
    normals: np.ndarray     # shape: (N_v, 3)
    faces: np.ndarray       # shape: (N_f, 3), uint32
    signs: np.ndarray       # shape: (N_v,), +1 or -1

def marching_cubes(
    volume: np.ndarray,
    isovalue: float,
    grid_origin: tuple[float, float, float],
    grid_spacing: tuple[float, float, float],
) -> IsosurfaceMesh:
    """Extract isosurface {r :  (r) = c} via scikit-image marching cubes.

    Vertices are translated to world coordinates by adding grid_origin.
    """
    ...
```

```python
def extract_dual_isosurface(
    volume: np.ndarray,
    isovalue: float,
    grid_origin: tuple[float, float, float],
    grid_spacing: tuple[float, float, float],
) -> IsosurfaceMesh:
    """Extract +c and -c isosurfaces; concatenate with sign tags.

    Positive-lobe vertices: sign = +1. Negative: sign = -1.
    Face indices of the negative mesh are offset by |V_pos|.
    """
    ...
```

(Full implementation: `report2_scripts/isosurface.py`)

9. `renderer.py`

Purpose: OpenGL renderer for orbital isosurfaces, PES curves, and molecular geometry.

This module provides the full 3D rendering pipeline using GLFW + OpenGL 3.3 Core Profile.

Function / Class	Description
`init_opengl_context(width, height, title)`	Initialises a GLFW window with an OpenGL 3.3 core-profile context, enables depth testing, 4× MSAA, and alpha blending. Returns the GLFW window handle.
`create_orbital_vao(mesh)`	Uploads an `IsosurfaceMesh` to the GPU. Vertex layout: `[x, y, z, nx, ny, nz, sign]` (7 float32 values, 28 bytes per vertex). Position at attribute location 0, normal at location 1, sign at location 2. Uses `GL_DYNAMIC_DRAW` since the mesh changes with bond length. Returns `(VAO, VBO, EBO, n_indices)`.
`update_orbital_vao(vbo, ebo, mesh)`	Orphans the old buffer and uploads new mesh data to the same VBO/EBO — a double-buffering strategy that avoids GPU sync stalls. Returns the new index count.
`create_pes_curve_vao(bond_lengths, energies_dict)`	Creates a VAO for rendering multiple PES curves as coloured line strips. Each method (HF, CISD, VQE, FCI, etc.) maps to a distinct RGBA colour. Vertices store `[R, E, 0, r, g, b, a]`. Returns `(VAO, VBO)`.

Function / Class	Description
`draw_molecule(atom_positions, atom_symbols, bonds, shader_program)`	Renders atoms as spheres and bonds as cylinders using instanced drawing of unit meshes. Atom colours follow the CPK convention (H = white, O = red, Li = purple, etc.) and radii are scaled van der Waals radii ($\times 0.3$).
`ArcballCamera`	Camera class supporting arcball rotation (left-drag), zoom (scroll), and heading/pitch angles. Computes view ($\mathbf{V}$ = lookAt) and perspective ($\mathbf{P}$) matrices for the shader pipeline.

```python
from __future__ import annotations

import ctypes

import glfw
import numpy as np
from OpenGL.GL import *

def init_opengl_context(
    width: int = 1400,
    height: int = 900,
    title: str = "VQE Molecular Explorer",
) -> object:
    """Init GLFW window with OpenGL 3.3 core profile, depth, MSAA, blending."""
    ...

def create_orbital_vao(
    mesh: IsosurfaceMesh,
) -> tuple[int, int, int, int]:
    """Upload IsosurfaceMesh to GPU.

    Vertex layout: [x, y, z, nx, ny, nz, sign] - 7 floats, 28 bytes.
    Returns (VAO, VBO, EBO, n_indices).
    """
    ...

def update_orbital_vao(
    vbo: int,
    ebo: int,
    mesh: IsosurfaceMesh,
) -> int:
```

```python
    """Orphan-and-reupload new mesh data to existing VBO/EBO.

    Returns new index count.
    """
    ...

def create_pes_curve_vao(
    bond_lengths: np.ndarray,
    energies_dict: dict[str, np.ndarray],
) -> tuple[int, int]:
    """Create VAO for PES curves as coloured line strips.

    Vertex layout: [R, E, 0, r, g, b, a] - 7 floats per vertex.
    Returns (VAO, VBO).
    """
    ...

def draw_molecule(
    atom_positions: np.ndarray,
    atom_symbols: list[str],
    bonds: list[tuple[int, int]],
    shader_program: int,
) -> None:
    """Render atoms as spheres (CPK colours, 0.3× vdW radii) and bonds as cylinders."""
    ...

class ArcballCamera:
    """Arcball camera: left-drag rotates, scroll zooms.

    Provides view (lookAt) and perspective (45°, near=0.1, far=200)
    matrices for the shader pipeline.
    """

    def __init__(
        self,
        position: np.ndarray | None = None,
        target: np.ndarray | None = None,
    ) -> None: ...

    def on_mouse_drag(self, dx: float, dy: float) -> None: ...

    def on_scroll(self, delta: float) -> None: ...

    def get_view_matrix(self) -> np.ndarray: ...
```

```
    def get_projection_matrix(self, aspect: float, fov: float = 45.0) -> np.ndarray: ...
```

(Full implementation: `report2_scripts/renderer.py`)

10. `hardware_runner.py`

Purpose: Submit VQE circuits to IBM Quantum or IonQ via PennyLane device plugins.

- **`HardwareVQEResult`** — Data class storing the measured energy, raw bitstring counts, shot count, hardware backend name, and the number of commuting Pauli groups measured.

Function	Description
`create_ibm_device(n_qubits, backend_name, shots, ibm_token)`	Creates a PennyLane device backed by the PennyLane-Qiskit plugin. Authenticates with an IBM Quantum API token (from argument or `IBMQ_TOKEN` environment variable). Default backend: `ibm_brisbane`, default shots: 8192.
`create_ionq_device(n_qubits, backend, shots, api_key)`	Creates a PennyLane device backed by the PennyLane-IonQ plugin. Default backend: `ionq_harmony` (simulator); switch to `ionq.qpu` for real hardware. Authenticates via argument or `IONQ_API_KEY` environment variable.
`estimate_shot_budget(hamiltonian, target_precision)`	Estimates the total number of shots S required to achieve standard deviation $\leq \epsilon$ on the energy estimate, using the variance bound $\mathrm{Var}[\hat{E}] \leq \sum_k \lvert c_k\rvert^2/S$ (assuming independent Pauli measurements). This gives $S \geq \sum_k \lvert c_k\rvert^2/\epsilon^2$. For H with $\sum \lvert c_k\rvert^2 \approx 0.3$ and $\epsilon = 1.6 \times 10^{-3}$ Ha, the bound yields $S \approx 117{,}000$. The result is clamped to $[1000, 10^7]$.

```
from __future__ import annotations

import os
from dataclasses import dataclass

import numpy as np
import pennylane as qml

@dataclass
class HardwareVQEResult:
    """Results from a hardware VQE execution."""
    energy: float
    raw_counts: dict[str, int]
    shots: int
    backend_name: str
    n_pauli_groups: int
```

```python
def create_ibm_device(
    n_qubits: int,
    backend_name: str = "ibm_brisbane",
    shots: int = 8192,
    ibm_token: str | None = None,
) -> qml.Device:
    """Create PennyLane device via qiskit.ibmq plugin.

    Authenticates with ibm_token or IBMQ_TOKEN env var.
    """
    ...

def create_ionq_device(
    n_qubits: int,
    backend: str = "ionq_harmony",
    shots: int = 1024,
    api_key: str | None = None,
) -> qml.Device:
    """Create PennyLane device via ionq.simulator plugin.

    Authenticates with api_key or IONQ_API_KEY env var.
    """
    ...

def estimate_shot_budget(
    hamiltonian: qml.Hamiltonian,
    target_precision: float = 1.6e-3,
) -> int:
    """Estimate shots S   Σ|c_k|² /  ² for energy precision  .

    Result clamped to [1000, 10 ].
    """
    ...
```

(Full implementation: `report2_scripts/hardware_runner.py`)

11. `benchmarker.py`

Purpose: Compare VQE results against classical methods across the PES.

- **`BenchmarkResult`** — Data class holding scanned bond lengths, list of method names, a dictionary of energy arrays keyed by method, correlation energy recovery ratios $r_{\text{corr}} = (E_{\text{method}} - E_{\text{HF}})/(E_{\text{FCI}} - E_{\text{HF}})$, and absolute errors $|E_{\text{method}} - E_{\text{FCI}}|$ for each method at every bond length.

`run_benchmark(pes_data)` takes a `PESData` object (from `scan_pes`) and computes, for every available method, the correlation energy recovery ratio and the absolute error relative to FCI. Division-by-zero is guarded at geometries where $E_{\mathrm{FCI}} \approx E_{\mathrm{HF}}$.

`print_benchmark_table(result, bond_lengths_subset=None)` formats the benchmark into a human-readable table showing R, each method's energy, and the VQE-vs-FCI error. If no subset is specified, five evenly spaced bond lengths are selected automatically.

```python
from __future__ import annotations

from dataclasses import dataclass

import numpy as np

@dataclass
class BenchmarkResult:
    """Results from a multi-method PES benchmark."""
    bond_lengths: np.ndarray
    methods: list[str]
    energies: dict[str, np.ndarray]
    correlation_recovery: dict[str, np.ndarray]
    errors_vs_fci: dict[str, np.ndarray]

def run_benchmark(pes_data: PESData) -> BenchmarkResult:
    """Compute correlation recovery ratio and |E - E_FCI| for each method.

    Division-by-zero guarded where |E_FCI - E_HF| < 1e-10.
    """
    ...

def print_benchmark_table(
    result: BenchmarkResult,
    bond_lengths_subset: np.ndarray | None = None,
) -> str:
    """Format benchmark as a human-readable table.

    Selects 5 evenly spaced bond lengths if no subset given.
    """
    ...
```

(Full implementation: `report2_scripts/benchmarker.py`)

12. `main.py`

Purpose: CLI entry point and workflow orchestration.

parse_args() defines the CLI interface via `argparse`. Supported flags include `--molecule` (`h2`, `lih`, `h2o`), `--basis` (e.g., `sto-3g`, `6-31g*`), `--bond-range` (`start,stop,n_points`), `--ansatz` (`uccsd` or `hardware_efficient`), `--optimizer` (`Adam`, `GradientDescent`, `COBYLA`, `SPSA`), `--maxiter`, `--hardware` / `--backend` for real-device execution, `--render` to enable the OpenGL viewer, `--benchmark` to compute all classical reference methods, `--orbital` for the MO index to visualise, and `--config` for a YAML configuration file.

run_pipeline(args) orchestrates the full workflow:

1. Parses the bond-range string into a `linspace` array.
2. Selects the appropriate molecule factory function.
3. Calls `scan_pes` to sweep bond lengths with VQE.
4. If `--benchmark` is set, calls `run_benchmark` and `print_benchmark_table`.
5. If `--render` is set, runs HF at equilibrium, evaluates the selected MO on a 3D grid, extracts the dual isosurface, and launches the OpenGL render loop with arcball camera interaction.
6. Prints a summary: equilibrium VQE energy, bond length, FCI energy, and absolute error.

```python
from __future__ import annotations

import argparse

import numpy as np

def parse_args() -> argparse.Namespace:
    """Define CLI: --molecule, --basis, --bond-range, --ansatz, --optimizer,
    --maxiter, --hardware, --backend, --render, --benchmark, --orbital, --config.
    """
    ...

def run_pipeline(args: argparse.Namespace) -> None:
    """Orchestrate: parse bond range → select factory → scan PES →
    benchmark (optional) → orbital render (optional) → print summary.
    """
    ...
```

(Full implementation: `report2_scripts/main.py`)

Part 3 — Implementation Guidelines (Instructional Pseudocode)

Module 1: `molecule.py`

```python
# --- molecule.py pseudocode ---
```

```python
def create_h2(bond_length=0.735):
    # Place two H on z-axis at ±R/2
    atoms = [
        Atom("H", np.array([0.0, 0.0, -bond_length / 2])),
        Atom("H", np.array([0.0, 0.0, +bond_length / 2])),
    ]
    return MoleculeSpec(atoms, basis="sto-3g", charge=0,
                        multiplicity=1, name=f"H2_R{bond_length:.3f}")

(Full implementation: `report2_scripts/main.py`)

Part 4 — OpenGL Visualization Design

1. Molecular Orbital Isosurface

VAO/VBO Layout

Each vertex stores 7 float32 values (28 bytes):

Offset	Attribute	Size	Description
0	Position	3 floats	(x, y, z) in Bohr
12	Normal	3 floats	Surface normal for lighting
24	Sign	1 float	$+1$ (positive lobe) or -1 (negative lobe)

The EBO stores triangle indices as uint32.

GLSL Shaders for the Isosurface

Vertex Shader (`orbital.vert`):

The vertex shader transforms each mesh vertex from object space to clip space via the standard $\mathbf{P} \cdot \mathbf{V} \cdot \mathbf{M}$ pipeline. It accepts three vertex attributes — position (x, y, z), normal (n_x, n_y, n_z), and lobe sign (± 1) — bound at locations 0, 1, and 2 respectively. The world-space position and the transformed normal (via the inverse-transpose of the model matrix, $\mathbf{n}' = (\mathbf{M}^{-T})\,\mathbf{n}$) are passed as varyings to the fragment stage.

(Full shader: `report2_scripts/shaders/orbital.vert`)

Fragment Shader (`orbital.frag`):

The fragment shader implements Phong shading with two-sided lighting (using $|\hat{\mathbf{n}} \cdot \hat{\mathbf{l}}|$ instead of $\max(0, \hat{\mathbf{n}} \cdot \hat{\mathbf{l}})$, so that back-faces of orbital lobes are visible). The lobe sign interpolated from the vertex stage selects the base colour: positive lobes are rendered in blue $(0.2, 0.4, 0.9)$ and negative lobes in red $(0.9, 0.2, 0.2)$, blended via `mix(negColor, posColor, (sign + 1)/2)`. A specular highlight with shininess exponent 32 and strength 0.4 is added. The final fragment is output with $\alpha = 0.7$ (semi-transparent) to allow visual inspection of internal structure.

Mesh Update on Bond Length Change

When the user moves a bond-length slider:

1. Recompute the MO at the new geometry: `evaluate_orbital_on_grid(...)` with updated atom positions.
2. Re-extract the isosurface: `extract_dual_isosurface(...)`.
3. Upload new mesh data via `update_orbital_vao(vbo, ebo, new_mesh)`.

To avoid stalls, use **double-buffered VBOs**: allocate two VBOs and alternate between them. When a bond-length change triggers recomputation (which can run on a background thread), the new mesh is uploaded to the inactive VBO. Once the upload completes, the active and inactive VBOs are swapped, giving a seamless transition with no pipeline stall.

(See `update_orbital_vao` in `report2_scripts/renderer.py`)

2. Potential Energy Surface Curve

The PES is rendered as a 2D curve in a 3D viewport, positioned to the side of the molecular orbital. For each method (HF, CISD, VQE, FCI, etc.), bond lengths are mapped to the x-axis and energies to the y-axis, with $z = 0$. Each method is drawn as a coloured `GL_LINE_STRIP` with a distinct RGBA colour (grey for HF, green for CISD, blue for VQE, gold for FCI, purple for CCSD(T)). Vertices store `[x, y, z, r, g, b, a]` (7 floats). The VBO is uploaded once per PES scan.

(See `create_pes_curve_vao` in `report2_scripts/renderer.py`)

A **moving marker** (small sphere) at the current bond length indicates which point on the PES corresponds to the displayed orbital.

3. Molecular Geometry

Atoms are rendered as spheres (using a tessellated icosphere VAO) and bonds as cylinders (using a tessellated tube VAO):

- Atom colours follow CPK convention (H=white, O=red, Li=purple, C=grey).
- Radii are scaled van der Waals radii ($\times 0.3$).
- Bond cylinders connect bonded atom pairs with radius ~ 0.1 Bohr.
- As the PES scan progresses, atom positions update and the molecular geometry animates smoothly.

4. Camera, Lighting, and UI Layout

Layout: The window is divided conceptually: - Left 2/3: 3D viewport with orbital isosurface and molecular geometry. - Right 1/3: PES curve plot and info panel (via Dear ImGui).

Lighting: A single directional light from above-right, plus ambient. The light position is fixed in camera space so it rotates with the view.

Camera: Arcball camera (see `ArcballCamera` class) with: - Left-drag: rotate - Scroll: zoom - Middle-drag: pan

ImGui Panel: The Dear ImGui overlay renders a side panel displaying the molecule name, basis set, current bond length, VQE and FCI energies, VQE–FCI error, and orbital index. A `slider_float` widget allows the user to drag the bond length between 0.3 and 3.0 Å, triggering `update_visualization(current_R)` whenever the value changes.

(See `report2_scripts/renderer.py` for the full render loop and ImGui integration.)

Part 5 — Hardware Execution Plan

1. IBM Quantum Submission via PennyLane

1.1 Circuit Transpilation and Qubit Layout

The PennyLane-Qiskit device handles transpilation automatically. To control the process, pass a `transpile_options` dictionary with `optimization_level` (0–3, where 3 performs the most aggressive gate cancellation and routing), and an `initial_layout` specifying which physical qubits to use (e.g., 4 qubits forming a line or star in the coupling map with minimal CNOT error). Use the `select_optimal_qubits` strategy from the QAOA report.

1.2 Pauli Grouping and Measurement Circuits

The H Hamiltonian has 15 Pauli terms. Not all can be measured simultaneously. Commuting Pauli terms can be grouped:

Commuting clique partitioning: Group Paulis that mutually commute (can be simultaneously diagonalised). For H :

- Group 1 (all Z-type): $\{I, Z_0, Z_1, Z_2, Z_3, Z_0Z_1, Z_0Z_2, Z_0Z_3, Z_1Z_2, Z_1Z_3, Z_2Z_3\}$ — all commute, measured in the computational basis.
- Group 2: $\{X_0X_1Y_2Y_3, Y_0Y_1X_2X_3\}$ — commute.
- Group 3: $\{X_0Y_1Y_2X_3, Y_0X_1X_2Y_3\}$ — commute.

This requires only 3 distinct measurement circuits instead of 15 separate ones.

PennyLane performs this grouping automatically when using `qml.expval(H)` with a hardware device. The `grouping_type` parameter (e.g., `"qwc"` for qubit-wise commuting) on `qml.Hamiltonian` controls the strategy.

1.3 Shot Budget for Chemical Accuracy

For the H Hamiltonian with $\sum_k |c_k|^2 \approx 0.3$ Hartree^2:

$$S \geq \frac{\sum_k |c_k|^2}{\epsilon^2} = \frac{0.3}{(1.6 \times 10^{-3})^2} \approx 117{,}000 \text{ shots}$$

With Pauli grouping (3 groups), distribute shots proportionally to the variance contribution of each group. In practice, 100,000–200,000 total shots (across all groups) suffices for chemical accuracy on H .

2. Error Mitigation for Chemistry

2.1 ZNE for VQE Energy

ZNE is particularly well-suited for VQE because: - The output is a scalar (energy), and ZNE extrapolates scalar values. - The noise in VQE circuits is dominated by incoherent errors (after Pauli twirling), which scale approximately linearly or polynomially with noise factor.

Apply ZNE exactly as described in the QAOA report (global unitary folding at scale factors 1, 3, 5 with Richardson extrapolation). For the H UCCSD circuit (depth ~16 CNOTs): - $\lambda = 1$: 16 CNOTs - $\lambda = 3$: 48 CNOTs - $\lambda = 5$: 80 CNOTs

At 80 CNOTs on ibm_brisbane ($\sim 0.5\%$ CNOT error), the total error probability is $\sim 33\%$, which is marginal but still within the regime where ZNE works. For deeper circuits (LiH, H O), ZNE may not suffice.

2.2 Symmetry Verification

Chemistry problems have symmetries that the exact ground state obeys: - **Particle number:** $\langle \hat{N} \rangle = N_e$ - **Spin:** $\langle \hat{S}_z \rangle = 0$ (for singlet states), $\langle \hat{S}^2 \rangle = 0$

Post-selection: discard measurement outcomes that violate these symmetries. This reduces the effective shot count but removes unphysical contributions. For H , filter the raw bitstring samples to keep only those whose Hamming weight equals N_e (the electron count), then recompute the energy expectation from the filtered sample set only.

2.3 Expected Performance

Configuration	$\lvert E_{\text{VQE}} - E_{\text{FCI}} \rvert$	Chemical accuracy?
H , noiseless sim	$< 10^{-6}$ Ha	Yes
H , noisy sim (1% depol)	~ 5 mHa	No
H , ibm_brisbane (raw)	~ 10–30 mHa	No
H , ibm_brisbane + ZNE	~ 2–5 mHa	Marginal
H , ibm_brisbane + ZNE + symmetry	~ 1–3 mHa	Possible

3. Comparison Checklist

Metric	Sim (noiseless)	Sim (noisy)	Hardware	HW + ZNE
E_{VQE} at R_e				
$\lvert E_{\text{VQE}} - E_{\text{FCI}} \rvert$				
Correlation recovery ratio				
PES shape (qualitative)				
Dissociation energy D_e				
Equilibrium R_e				
VQE iterations to converge			—	—
Total circuit evaluations				

Plots to produce: 1. PES: $E(R)$ for HF, CISD, CCSD(T), VQE, FCI on same axes. 2. Error: $\lvert E_{\text{method}} - E_{\text{FCI}} \rvert$ vs R for each method. 3. Correlation recovery ratio vs R. 4. VQE convergence: energy vs iteration at R_e and at $R = 3.0$ Å.

Part 6 — Benchmarking & Validation

1. Validation Against PySCF FCI

To validate VQE energies, a helper function builds a PySCF `Mole` from the `MoleculeSpec`, runs RHF + FCI to obtain the exact ground-state energy E_{FCI}, and computes the absolute error $\Delta E = |E_{\text{VQE}} - E_{\text{FCI}}|$. The error is reported in Hartree, milliHartree ($\times 1000$), and kcal/mol ($\times 627.509$). Chemical accuracy ($\Delta E < 1.6 \times 10^{-3}$ Ha) is flagged with a boolean.

(Full implementation: `report2_scripts/benchmarker.py` and `report2_scripts/classical_hf.py`)

2. Metrics to Measure and Plot

Correlation energy recovered:

$$r_{\text{corr}} = \frac{E_{\text{VQE}} - E_{\text{HF}}}{E_{\text{FCI}} - E_{\text{HF}}}$$

A value of $r_{\text{corr}} = 1.0$ means VQE recovers all correlation energy.

State fidelity: If the VQE state $|\psi_{\text{VQE}}\rangle$ and exact ground state $|\psi_0\rangle$ are both available (in simulation):

$$F = |\langle \psi_{\text{VQE}} | \psi_0 \rangle|^2$$

In PennyLane, extract the statevector via `qml.state()` and compute overlap with the FCI eigenvector.

Circuit depth vs accuracy:

UCCSD layers	CNOT depth (H)	$\lvert E - E_{\text{FCI}}\rvert$
1 Trotter step	~16	$< 10^{-6}$
2 Trotter steps	~32	$< 10^{-8}$

For H , a single Trotter step of UCCSD is exact (the ansatz is expressible). For LiH and H O, multiple Trotter steps improve accuracy.

3. Results Table Template

R (Å)	E_{HF}	E_{CISD}	$E_{\text{CCSD(T)}}$	E_{VQE}	E_{FCI}	$\lvert E_{\text{VQE}} - E_{\text{FCI}}\rvert$
0.50						
0.75						
1.00						
1.50						
2.50						

Part 7 — Research Contribution Angle

1. Three Directions Toward a Publishable Result

Direction 1: Adaptive Ansatz PES — ADAPT-VQE vs UCCSD Across Dissociation

Implement ADAPT-VQE (Grimsley et al., 2019), which builds the ansatz one operator at a time by selecting the operator with the largest gradient at each step. Compare the PES from ADAPT-VQE vs fixed UCCSD across the full dissociation curve for H , LiH, and BeH . Key questions: Does ADAPT-VQE use fewer parameters? Is the PES smoother? Does it handle the multi-reference region (near dissociation) better? Benchmark circuit depth and parameter count at each bond length.

Direction 2: Noise-Aware VQE for Robust PES

Study how noisy VQE distorts the PES and propose corrections. At each bond length, run VQE under varying noise strengths and measure: (a) equilibrium bond length shift, (b) dissociation energy error, (c) PES curvature distortion (affects vibrational frequencies). Propose a noise-aware cost function $\tilde{E}(\theta;\lambda) = E_{\text{noisy}}(\theta) - f(\lambda)$ where $f(\lambda)$ is a noise correction learned from ZNE. Show that this gives a more accurate PES than raw noisy VQE.

Direction 3: SHARC-VQE Partitioned Hamiltonian Benchmarking

Implement the SHARC (Singlet-Triplet Hamiltonian Arithmetic) partitioning from Ralli et al. (2023), which splits the molecular Hamiltonian into fragments that can be solved independently on smaller quantum devices. Benchmark the partitioned approach vs monolithic UCCSD for H O and small organic molecules (methane, ethylene). Measure the accuracy-vs-resource tradeoff and identify the optimal partitioning strategy for NISQ hardware.

3. Tractable Molecules on Today's Hardware

Molecule	Qubits (STO-3G)	Qubits (6-31G*)	Active Space	Tractable?
H	4 (2 tapered)	8	Full	Yes (demonstrated)
LiH	12 (10 tapered)	22	(2e, 5o) → 10 qubits	Yes with active space
BeH	14	26	(4e, 6o) → 12 qubits	Marginal
H O	14 (12 tapered)	38	(4e, 4o) → 8 qubits	Yes with active space
NH	16	40	(6e, 6o) → 12 qubits	Marginal
N	20	48	(6e, 6o) → 12 qubits	Marginal (strong corr.)

Why active space is essential: The full orbital space is far too large for current hardware. Active space methods freeze core electrons and discard high-energy virtual orbitals, reducing the qubit count to a tractable number. The active space must be carefully chosen to include the orbitals involved in bond-breaking (the valence space).

N is the holy grail: The triple bond in N involves strong static correlation across 6 electrons in 6 orbitals. Accurately computing the N PES is a long-standing challenge for both classical and quantum methods. Demonstrating VQE on N with an active space of (6e, 6o) on 12 qubits would be a significant milestone.
